Abstract

Low efficiency is the main drawback of many MEMS thermal energy harvesters. Recently, energy harvesting micro-devices that operate using the pyroelectric effect gained attention due to their potential superior performance. Operation of these devices is based on the cyclic motion of a pyroelectric capacitor that operates between a high temperature and a low temperature reservoirs. In this paper, we investigate the dynamics of oscillations of a pyroelectric capacitor self sustained by thermally actuated bimetal micro-cantilevers, a topic which is so far under investigated. In addition to highlighting key thermodynamic aspects of the operation, we explore conditions for self-sustained oscillations and discuss the viability of operation at the mechanical resonance frequency. The analysis is presented for a new design inspired by the device proposed in Hunter *et al* (2011 *SPIE Defense, Security, and Sensing* (International Society for Optics and Photonics) p 80350V); Hunter *et al* (2012 *SPIE Defense, Security, and Sensing* (International Society for Optics and Photonics) p 83770D), where in contrast, our proposed design boasts the following features: the pyroelectric capacitor remains parallel to the heat reservoirs, by virtue of its symmetric support by two bimetallic cantilever beams; in addition, the cyclic operation of the device does not require physical contact, thus lowering the risk of mechanical failure. To adjust the damping force imparted by the surrounding gas, the thermal reservoirs are equipped with trenches. To study the dynamic operation of the device, we developed a physically based reduced order, yet accurate, model that accounts for the heat transfer between and within the different components, and for the various forces including the gas damping force. The model is embedded within an optimization algorithm to produce optimal designs over the range 26 °C–38 °C of temperature difference between the two reservoirs. The corresponding range of harvested power density is 0.4–0.65 mW cm^{-2}.

1. Introduction

It has been reported that a substantial amount of the consumed energy in the USA is wasted as heat [3, 4]. Therefore, considerable research effort has been directed towards harvesting energy from these waste sources. This in turn would offer a long lasting green power and maintenance-free devices. Most of the research in this domain has been focused on utilizing thermoelectric materials which rely on the spatial gradient of temperature (dT/dx). This temperature gradient can be easily realized without the need for moving parts, which is a desirable design feature. Thermoelectric devices are, however, not suited for applications where the temperature is below 100 °C [4]. Moreover, extensive research on thermoelectric generators showed that their efficiency could not exceed 1%–5% [1]. In contrast, pyroelectric devices, which rely on the time variation of the temperature (dT/dt) for power conversion, can achieve a similar efficiency at lower temperatures (or higher efficiency for similar operating temperatures) [1, 2]. The time variation of the temperature is realized by cyclic motion of the pyroelectric capacitor operating between a high and a low temperature reservoirs.

It is worth noting that the efficiency of pyroelectric devices is greatly affected by their operation frequency. That is the closer the frequency to the mechanical resonance frequency, the higher the device efficiency. The operation frequency in bulk devices is expected to be in the order of 1–5 Hz, which is orders of magnitude below the resonance frequency. This is due to limitations in the diffusion-based heat transfer processes and/or others imposed by the actuation mechanism. In order to increase the operation frequency, heat exchange between the pyroelectric capacitor and the thermal reservoirs should be sufficiently fast. This can be accomplished by reducing the gap separating the capacitor and the heat source (sink) to the submicron length scale [5], causing the much faster radiative heat transfer to be the dominant mode of heat transfer. It has also been proposed to use thin films as a simple means to improve the heat transfer rate [6]. Equally important for fast operation of the device is the speed of the actuation mechanism. Self sustained cyclic motion of the pyroelectric plate using thermally actuated bimetal cantilevers is proposed in [1, 2]. In this case, heat transfer by conduction along the bimetal cantilevers is a speed limiting mechanism. Alternatively, actuation through piezoelectric nano-pillars is proposed in [6]. Although fast, this actuation method requires electric input work for actuation which, for acceptable values of the overall efficiency (or net generated work), yields small displacements of the pyroelectric capacitor. This, in turn, keeps the distance between the plate and the heat source/sink relatively large, which limits the heat exchange rate. This may explain why the operation frequency does not exceed 10 Hz which is well below the natural frequency of the device [6].

Self sustained oscillations (SSO) of piezo-electrically actuated micro-cantilevers have been widely used in many MEMS devices such as photo-detectors [7], atomic force microscopy [7] and sensors [8–10]. In these systems, the oscillator is usually made from a single metallic or semiconducting material and their vibratory behaviors in different environments (air,

liquid and even vacuum) are well understood [11]. However, the literature is lacking when it comes to the analysis of gas-damped SSO of bimetal cantilevers actuated by cyclic temperature variation, such as those encountered in pyroelectric microdevices. It is therefore of paramount importance for reliable design of such systems to investigate their dynamic behavior. It is well documented that at nano/micro-scale, the performance of microdevices with vibrating components is strongly affected by the viscous damping due to their interaction with the surrounding fluid. In parallel plate MEMS capacitors, for example, the distance between the capacitor plates is usually minimized for improved efficiency [12]. This potentially may result in non-continuum fluid-solid interaction due to the formation of squeezed film damping.

In this paper, we propose a new pyroelectric micro energy harvester. We use the proposed device to investigate the dynamics of thermally induced self sustained oscillations of bimetal micro-cantilevers using a physically-based reduced order, yet accurate, model that we developed for this purpose. The model accounts for the heat transfer between and within the different components, and for the various forces including the damping force induced by the squeezed gas film. We then employ this model within an optimization loop to arrive at nearly optimal dimensions of the proposed design over a range of the temperature difference between the high and low temperature reservoirs. The proposed design is inspired by the device proposed in [1, 2], which consists of a proof mass supported by a bimaterial canitlever that serves at the same time as the pyroelectric capacitor. The proof mass which oscillates between the high and low temperature reservoirs serves as a thermal capacitor that stores heat when it contacts the high temperature reservoir (HTR) and loses heat when it contacts the low temperature reservoir (LTR). The oscillation, which generates an electrical current in the pyroelectric capacitor, is actuated by the downward and upward bending of the bimorph cantilever as a result of heat transfer from the proof mass to the bimaterial cantilever and vice versa. Our proposed device was designed, in part, to overcome the following limitations in the device proposed in [1, 2]. The asymmetrical shape of the device requires tilting of the proof mass so that contact with the reservoir walls occurs over a small area. This design limits the rate of heat transfer between the proof mass and the thermal reservoirs due to the resulting high contact thermal resistance. In addition, direct contact over a large number of operation cycles may lead to failure [13–15]. Moreover, heat gained by the proof mass upon contact with the HTR flows in the pyroelectric capacitor along its length. The resulting pyroelectric effect, which depends on the spatial distribution of the temperature variation with time decreases along the bimetal cantilever length away from the capacitor.

This paper is organized as follows. The proposed design is presented in section 2. In section 3, we highlight key thermodynamic aspects of the operation. The reduced order model we developed to design the device and investigate its dynamic operation is presented in section 4. Dynamic operation of the device is investigated in section 5. In section 6, we outline key design considerations, discuss conditions for sustained oscillations, and present a simple design procedure for device
Figure 1. The proposed pyroelectric energy harvester in a 3D-model isometric view (top) and in a section view (bottom) where the pyroelectric element, subjected to an electric field, is connected to an electric load.

operation at the mechanical resonance frequency. Assessment of the validity and accuracy of the model is conducted in section 7. Optimized designs and trends characterizing key performance indicators including the energy output are presented in section 8.

2. The proposed device

The proposed device, which has a symmetric design, is presented in figure 1. The pyroelectric capacitor, shaped as a rectangular plate of large area in the $x - y$ plane, is connected to the bimetal cantilevers by means of four tethers. Since heat exchange between the pyroelectric capacitor and the heat reservoirs takes place directly over a large area (in the $x - y$ plane), the time it takes to thermally charge and discharge the capacitor is very small. This, in addition to designing the tethers to have sufficiently large thermal resistance, guarantees a nearly spatially uniform temperature distribution in the pyroelectric capacitor at all times. The tethers are also designed to have low torsional and bending stiffness which allows them to rotate about their axis (along the y direction) and bend in the x-direction with negligible effect on the pyroelectric plate so that it remains rigid and horizontal during the actuation.

Each bimetal cantilever is composed of two metals of different heat expansion coefficients which force it to bend with temperature variation. When the pyroelectric capacitor gets in contact with the HTR, its temperature rises (approaching that of the HTR) and heat diffuses toward the bimetal cantilever through the tethers. Choosing the upper layer metal to have the higher heat expansion coefficient forces the cantilever to bend downward and push the pyroelectric plate toward the the LTR. Upon contact with the LTR, the pyroelectric plate temperature

decreases approaching that of the LTR. As the cantilevers cool down, they bend upward. The cycle starts again when the plate reaches the HTR.

In addition, the proposed design of figure 1 does not require direct (solid-solid) contact between the capacitor and the reservoirs. We assume that the plate stops when it gets within a distance of $g_{min}/2$ from either reservoir. Although this results in reduction in the output power and efficiency due to the additional thermal resistance of the gas film (of thickness $g_{min}/2$), this sacrifice alleviates all the challenges associated with physical contact, and as such increases the life of the device. Although we do not discuss the stopping mechanism in this work, we point out that it is possible, in theory, to design the device such that it oscillates in an autonomous fashion without hitting either reservoir and without the need for an additional stopping mechanism.

3. Thermodynamics model

A pyroelectric material is a special type of piezoelectric materials [16] that undergoes spontaneous polarization when its temperature varies in time. In engineering applications, the pyroelectric material is typically oriented along the principal crystallographic direction [17, 18]. In the presence of an external electric field, E_f, applied along the same direction, the pyroelectric effect is quantified in terms of the generalized pyroelectric coefficient, $\pi = \partial D / \partial T$, measuring the increase in the surface charge density[3], $D = \mathscr{E} E_f + \Pi_s$, per unit increase in the temperature:

$$\pi = \pi_s(T) + E_f \frac{\partial \mathscr{E}}{\partial T} \tag{1}$$

where

$$\pi_s(T) = \frac{\partial \Pi_s}{\partial T} < 0 \text{ for } T < T_C. \tag{2}$$

Π_s is the spontaneous polarization, T is the temperature, T_C is the Curie temperature, and $\mathscr{E}$ is the electrical permittivity of the pyroelectric.

The current I_π flowing to the external circuit, shown in figure 1, is then expressed as:

$$I_\pi = A \frac{\partial D}{\partial t} = A \pi \frac{dT}{dt} \tag{3}$$

where A is the area of the electrode plates. It should be noted that the effect of permittivity variation with temperature can be comparable to the spontaneous pyroelectric effect π_s and can also be seen above the Curie point [16].

As the plate, shown in figure 1, travels back and forth between the HTR and the LTR, the pyroelectric material (sandwiched between the capacitor electrodes), undergoes the Ericsson cycle shown shown in figure 2. The thermodynamic cycle and voltage control, presented next for the sake of completeness and clarity of the observations we make at the end of this section, are well described in [1, 2]. The four processes that make

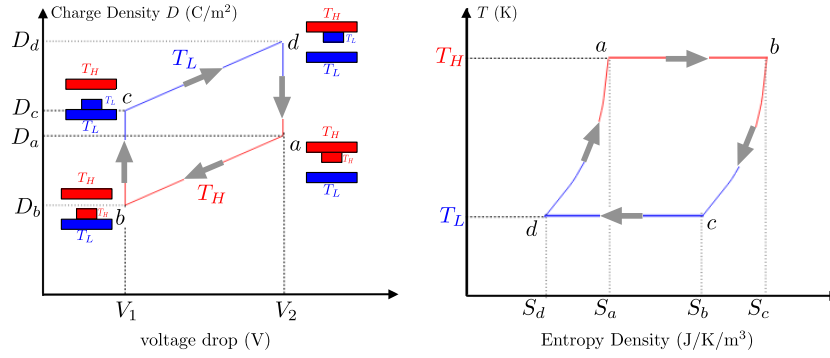

Figure 2. Ericsson cycle of the pyroelectric material shown on charge voltage diagram [1, 2].

up the cycle are as follows. (1) Process $a \to b$ is an isothermal process, where the pyroelectric element, of temperature that has just reached T_H by receiving heat from the HTR (state a), is deflected by the bimetal cantilevers to state b, where the pyroelectric element has just been brought in thermal contact with the LTR. During this process, the voltage drops from $\mathscr{V}_2$ to $\mathscr{V}_1$. The voltage is controlled by a sensor as described in [1]. The heat gained by the pyroelectric element per unit volume during this isothermal process is $q^{\leftarrow}_{a \to b} = |\pi| T_H \frac{\mathscr{V}_2 - \mathscr{V}_1}{t_c}$, where t_c is the thickness of the pyroelectric element. (2) Process $b \to c$ is a constant voltage process during which heat is transferred from the pyroelectric element to the LTR. The heat lost per unit volume is $q^{\to}_{b \to c} = c_E (T_H - T_L)$, where c_E is specific heat of the pyroelectric element. (3) Process $c \to d$ is an isothermal process during which the pyroelectric element, at T_L, is pulled back toward the HTR by the bimetallic cantilevers as they unbend due to cooling. The heat lost by the pyroelectric element per unit volume during this isothermal process is $q^{\to}_{c \to d} = |\pi| T_L \frac{\mathscr{V}_2 - \mathscr{V}_1}{t_c}$. (4) Process $d \to a$ is a constant voltage during which heat is transferred from the HTR to the pyroelectric element. The heat gained per unit volume is $q^{\leftarrow}_{d \to a} = c_E (T_H - T_L)$. With $\frac{\mathscr{V}_2 - \mathscr{V}_1}{t_c} = E_{f2} - E_{f1}$, the net work produced per cycle is then

$$W^{\to}_{\text{cycle}} = A_c t_c |\pi| (T_H - T_L)(E_{f2} - E_{f1}). \tag{4}$$

The power production is then the product of $W^{\to}_{\text{cycle}}$ and the cycling frequency f,

$$\dot{W}^{\to} = f A_c t_c |\pi| (T_H - T_L)(E_{f2} - E_{f1}). \tag{5}$$

The thermodynamic efficiency is

$$\eta = \frac{w^{\to}}{q^{\leftarrow}_{d \to a}} = \eta_C \frac{1}{1 + \beta \eta_C} \tag{6}$$

where the Carnot efficiency is $\eta_C = 1 - \frac{T_L}{T_H}$ and

$$\beta = \frac{c_E t_c}{|\pi|(\mathscr{V}_2 - \mathscr{V}_1)} = \frac{c_E}{|\pi|(E_{f2} - E_{f1})}. \tag{7}$$

Pyroelectric properties of high-quality $(0\,0\,0\,1)$AlN films grown on $(1\,1\,1)$ Si were experimentally measured using the dynamic method in [19]. The reported value of the pyroelectric coefficient was in the range of 6–8 μC (m^2 K)$^{-1}$, over

a temperature range of 15 °C–35 °C. With $\mathscr{E}_r = 8.5$ at room temperature [20], the corresponding range of the $p/\mathscr{E}_r$ figure-of-merit is 0.8–0.95. The pyroelectric coefficient studied in [19] was independent of temperature and applied bias. The specific heat of AlN is $c_E = 734$ J kg^{-1} °C^{-1} [21]. In [22], the reported range of values of the pyroelectric coefficient, measured experimentally at room temperature (298 °K), is 10–12 μC (m^{2}K)$^{-1}$. Dependence of the relative permittivity on the temperature can be inferred from [23], where the variation of the capacitance with temperature was studied. Over a temperature range of 25 °C–50 °C, $\mathscr{E}_r$ decreases with T as $\frac{d\mathscr{E}_r}{dT} \simeq -1.2147 \times 10^{-3}$ °K^{-1}. With $\mathscr{E} = \mathscr{E}_r \mathscr{E}_0$, the pyroelectric coefficient, expressed in equation (1), may be approximated as $\pi \simeq \pi_s$, given that the electric field should not exceed the dielectric strength.

Upon inspecting equations (4)–(7), we make the following observations. Assessing the efficiency of the pyroelectric device as a heat engine is dependent on the nature of the HTR as an energy source, given that the LTR is an infinite sink; i.e. it maintains its temperature. If the HTR is an infinite source, i.e. it maintains its temperature at all times as it exchanges heat with the pyroelectric element, then the frequency of operation is more important than how close the efficiency is to the Carnot efficiency. For given T_H, T_L, and pyroelectric material properties (π and c_E), the ratio of η/η_C can be increased by increasing $E_{f2} - E_{f1}$. AlN possesses a relatively high dielectric strength [21] of $E_{f,Break} = 17$ kV $\cdot$ mm^{-1}. This property allows applying large electric field difference in the Ericsson's cycle leading to large voltage difference. For $E_{f2} - E_{f1} < E_{f,Break}$, $\beta > \beta^\star$, where $\beta^\star = \frac{c_E}{|\pi| E_{f,Break}} = 6.55$. It can be observed from equation (6) that $\eta \to \eta_C$ for $\eta_C \beta \ll 1$ (or $\frac{T_L}{T_H} \gg 1 - \beta^{\star-1}$) and $\eta \to \frac{1}{\beta^\star}$ for $\eta_C \beta \gg 1$ (or $\frac{T_L}{T_H} \ll 1 - \beta^{\star-1}$). For $T_L = 10$ °C and $T_H = 34$ °C, $\eta_C = 0.0781$ and $\eta = 0.66\eta_C$. For given T_H, T_L, pyroelectric material properties (p and c_E), and $E_{f2} - E_{f1}$, the power production (equation (5)) can be increased by increasing the operation frequency, f, and the volume of the pyroelectric capacitor $A_c t_c$. Note that a smaller thickness of the capacitor implies that one needs to apply a lower voltage across the capacitor, for given value of the E_f. Another key aspect of assessing the performance is whether the power output should be reported per unit area of the device or per unit volume. Reporting the power density as the power output per unit volume may make more sense because it takes
Figure 3. Representative meshes used in the reduced order model for the heat transfer (capacitor, tethers, and bimorphs) and the squeezed film (trenched thermal reservoirs).

Figure 4. Schematic of the bimetal cantilever.

into account the distance between the HTR and the LTR. It is also more representative than the surface density when the devices are stacked. The power produced per unit volume is

$$\dot{\omega}^{\rightarrow} = \frac{fL_c t_c |\pi| (T_H - T_L)(E_{f2} - E_{f1})}{(L_c + 2L_b)H}. \tag{8}$$

Note that T_H and T_L are the maximum and minimum average temperature of the pyroelectric capacitor over a cycle.

4. The reduced order model

Reduced order modeling [24] is an essential tool to make affordable the cost of computer-based design cycles. In this section, we present the reduced order model of the thermo-mechanical dynamic operation. The model also accounts for the damping forces imparted on the capacitor by the surrounding gas. The model is validated by comparing it with detailed numerical simulations using Ansys, as presented in section 7. Being two orders of magnitude faster, the reduced order model is used to optimize the design over wide ranges of design parameters. To this end, the model is embedded within an optimization algorithm to estimate the dimensions that maximize the power produced per unit volume for a given temperature difference between the HTR and the LTR.

The motion of the pyroelectric capacitor, assumed to be rigid of mass m_c and position z_c, is governed by

$$m_c \frac{d^2 z_c}{dt^2} = F_{tip}(\Delta T, z_{tip}) + F_{torsion} + F_{damping} \tag{9}$$

where $F_{tip}(\Delta T, z_{tip})$ is the thermo-mechanical force imparted by the bimetal cantilevers, $F_{torsion}$ is the torsion force imparted by the tethers, and $F_{damping}$ is the damping force imparted by the surrounding gas. The thermo-mechanical force imparted by the bimetal cantilevers on the capacitor takes into account the deformation due to thermal expansion (contraction) caused by temperature changes. Next, we present models for calculating these forces along with the temperature distribution in the device. Numerical solution of the model equations requires spatial discretization of the different elements, as depicted in figure 3.
4.1. Forces by the bimetal cantilever and the tethers

In this section, we present an expression for the force exerted by the bimetal cantilevers on the pyroelectric capacitor. We choose the tethers to be sufficiently compliant so that the horizontal force is small compared to the vertical force. This requires the bending stiffness of the tethers in the horizontal x-direction to be small compared to the bending stiffness in the vertical z-direction, i.e. $(b/t)_t \ll 1$. The distance between the tethers and the pyroelectric capacitor must be sufficiently large to provide the needed room for bending. The vertical force exerted by the beams on the pyroelectric capacitor is a function of their temperatures and tip deflections. The (downward) force at the tip of the bimetal cantilevers is the sum of a linear spring component and a thermal expansion component

$$F_{tip}(\Delta T, z_{tip}) = (z_{tip} - z_{tip,exp}) \frac{3(EI)_{eq}}{L_b^3} \tag{10}$$

where $z_{tip,exp}$ is the tip deflection induced by thermal expansion. For a spatially uniform temperature distribution $z_{tip,exp} = \frac{KL_b^2}{2}$, where the curvature, K, of the bimetal cantilever due to thermal expansion can be found in [25]

$$K = \frac{6b_1 b_2 E_1 E_2 t_1 t_2 (t_1 + t_2)(\gamma_2 - \gamma_1)\Delta T}{(b_1 E_1 t_1^2)^2 + (b_2 E_2 t_2^2)^2 + 2b_1 b_2 E_1 E_2 t_1 t_2 (2t_1^2 + 3t_1 t_2 + 2t_2^2)}, \tag{11}$$

$(EI)_{eq}$ is the equivalent flexural rigidity and ΔT is the change in temperature of the bimetal cantilevers from a reference value, T_0, for which $K = K_0 = 0$. The various dimensions in equation (11) are depicted in figure 4. The equivalent flexural rigidity, $(EI)_{eq}$, is

$$(EI)_{eq} = E_1 \left[\frac{b_1 t_1^3}{12} + \left(\frac{t_1 + t_2}{2} - c \right)^2 b_1 t_1 \right] + E_2 \left[\frac{b_2 t_2^3}{12} + c^2 b_2 t_2 \right] \tag{12}$$

where c, the location of the common neutral axis relative to the axis of the lower beam, is

$$c = \frac{E_2 b_2 t_2 t_1}{E_2 b_2 t_2 + E_1 b_1 t_1}. \tag{13}$$

Table 1. Materials (and their properties) selected for the bimetal cantilever layers, tethers, and pyroelectric capacitor.

Table 2. Device dimensions (μm) used for discussing device operation, design consideration, and for comparing the model to Ansys FSI simulations.

	Bimetal cantilever layer 1	Bimetal cantilever layer 2	Tethers	Pyroelectric capacitor
Length L	1000	1000	20	1000
Width b	20	20	2	140
Height t	2.5	2.5	5	8

Since the heat transfer in the bimetal cantilever is slow compared to that in the pyroelectric capacitor, the temperature distribution along the bimetal cantilever is non-uniform. In this case, the beam is discretized into a number of elements each of which assumes a uniform temperature. The tip deflection, arising from thermal expansion, is obtained as

$$z_{tip,exp} = \frac{L_b^2}{n^2}\left[\frac{K_n}{2} + \frac{3}{2}\sum_{i=1}^{n-1} K_i + \sum_{i=1}^{n-2}\sum_{j=1}^{i} K_j\right], \quad n \geqslant 3 \quad (14)$$

where the curvature K_i of element i is calculated from equation (11).

Since the bimetal cantilever is connected to the plate through the tethers, it is necessary to factor in the impact of the tethers on the force at the tip of the bimetal cantilever. The contribution of the tethers to this force can be divided into two independent torsional and bending components. Torsion of the tethers occurs due to the bending of the bimetal cantilever while the pyroelectric plate stays horizontal (due to symmetry) as it shuttles back and forth between the two thermal reservoirs. At the same time, the tethers experience bending in the *x*-direction caused by the thermal expansion/contraction of the bimetal cantilever. Since the tethers are designed so that this bending compliance is large, we neglect the associated horizontal force component on the bimetal cantilever tip, as discussed at the beginning of this section. The tethers torque, $\mathscr{T}$, is transformed to a bending moment on the tip of the bimetal cantilever element. The equivalent vertical force at the tip of the bimetal cantilever that yields the same tip displacement as that due to the moment, assuming small deflections, is

$$F_{\text{torsion}} = \frac{3}{2}\frac{\mathscr{T}}{L_b}, \quad \mathscr{T} = \left(\frac{JG}{L}\right)_t \theta \quad (15)$$
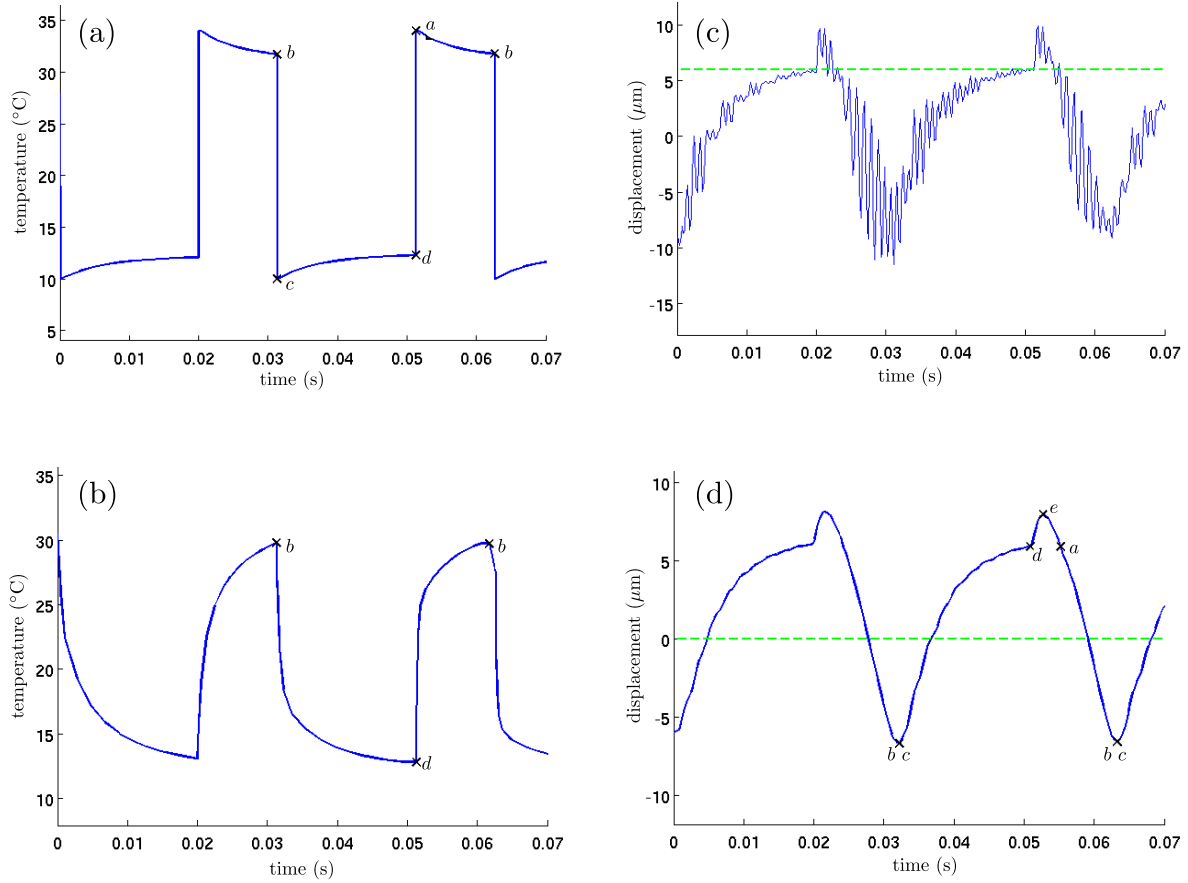

where G is the shear modulus, L_t is the length the tether, θ is the angle of twist at the tip of the tether and $J \simeq tb^3\left(\frac{1}{3} - 0.21\frac{b}{t}\left(1 - \frac{b^4}{12t^4}\right)\right)$ ([26]).

4.2. Gas damping

In order to realize the desired damping force for optimal performance of the device, the HTR and the LTR are patterned with trenches, as shown in figure 1. In arriving at the optimized designs presented in section 8, the trench width and depth are adjusted so that the pyroelectric plate is sufficiently damped while maximizing the produced energy.

The motion of the pyroelectric capacitor is such that it remains parallel to the thermal reservoirs. In addition, the gap (g) separating the capacitor and each of the reservoirs is much smaller than the plate length (L_c) and width (b_c). At an operation frequency of $f = 60$ Hz, the average plate speed is $V_c = 2Hf = 0.0024$ m s^{-1}. The average speed at which the air is pushed as the plate squeezes the air film is then $V = V_cL_cb_c/(\Pi_cH) = 0.0074$ m s^{-1}, where $\Pi_c = 2(L_c + b_c)$ is the plate perimeter. The Reynolds number of the flow is $\text{Re} = VH/\mu' = 0.01$, where $\mu' = 1.48 \times 10^{-5}$ m^2 s^{-1} is the kinematic viscosity of air at atmospheric conditions. Since $\text{Re} \ll 1$, the flow can be modeled as inertia free. In addition, the flow is assumed to be isothermal. This assumption is justified on the grounds that viscous dissipation does not lead to any appreciable temperature rise and that, in non-insulated micro-devices, the heat generated will be lost quickly due to the large surface to volume ratio. The fact that the squeezed film thickness (the gap separating the pyroelectric plate from either reservoir) is much larger than the mean free path, λ, of air (at the thermodynamic state corresponding to the enclosure pressure and ambient temperature) implies that the flow is in the continuum regime, i.e. $\text{Kn} = \lambda/H \ll 1$. The only exception is when the pyroelectric plate gets too close (a few mean free paths) to either reservoir. Under the assumptions of isothermal and inertia-free flow in the continuum regime, we can use the lubrication theory whereby the pressure, $p(x, y, t)$, of the air film between the pyroelectric plate and either reservoir is governed by the Reynolds equation

$$\frac{\partial(pg)}{\partial t} = \frac{1}{12\mu'}\left[\frac{\partial}{\partial x}\left(pg^3\frac{\partial p}{\partial x}\right) + \frac{\partial}{\partial y}\left(pg^3\frac{\partial p}{\partial y}\right)\right] \quad (16)$$

Figure 5. Ansys simulation results of (a) the temperature variation at the center of the capacitor, (b) the temperature variation at a point of a bimetal cantilever 200 μm away from the capacitor, the capacitor center displacement while the device is operating with the absence (c) and presence (d) of damping.

Table 3. Dimensions of optimized designs for different $T_H - T_L$. For all the designs, the width of the capacitor, minimum gap size, trench width were fixed: $b_c = 50\ \mu m$, $g_{min} = 0.5\ \mu m$, $b_{tr} = 25\ \mu m$, $X = 1 - b_{tr}/a$, $t_c = H - 2\ \mu m$. Note that the smallest dimension is the tether width b_t, with $0.75\ \mu m \leqslant b_t \leqslant 1\ \mu m$. All dimensions are in μm and temperatures in °C.

where $g(x, y, t)$ is the gap separating the pyroelectric plate and the thermal reservoir (see figure 1), and μ' is the effective viscosity [27, 28], expressed as $\mu' = \frac{\mu}{1 + 9.638\,\mathrm{Kn}^{1.159}}$.

We assume that the change in pressure, $\hat{p}$, introduced by the motion of the pyroelectric capacitor is a small compared to the unperturbed enclosure pressure, p_0. Then for $p = p_0 + \hat{p}$, $\hat{p} \ll p_0$, equation (16) is approximated as

$$\frac{\partial g}{\partial t} = \frac{1}{12\mu} \left[\frac{\partial}{\partial x} \left(g^3 \frac{\partial \hat{p}}{\partial x} \right) + \frac{\partial}{\partial y} \left(g^3 \frac{\partial \hat{p}}{\partial y} \right) \right]. \quad (17)$$

The damping force acting on the plate is then computed by integrating, over the area of the pyroelectric capacitor area, the difference in pressure between the bottom and top surfaces

$$F_{\text{damping}} = \int_{W_p} \int_{L_p} (\hat{p}_b(x, y, t) - \hat{p}_t(x, y, t))\ dxdy. \quad (18)$$

Since pyroelectric plate travels the entire distance separating the two reservoirs, solutions based on the linearized Reynolds equation [29] for small displacements are not applicable here. The nonlinear partial differential equation (17) is numerically solved in each of the two gas film domains between the capacitor and the two thermal reservoirs. The numerical method uses an explicit first order time integration scheme with second order finite difference discretization of the spatial derivatives. Figure 3 shows an example of the mesh used to represent the surface of the trenched thermal reservoirs when solving equation (17).
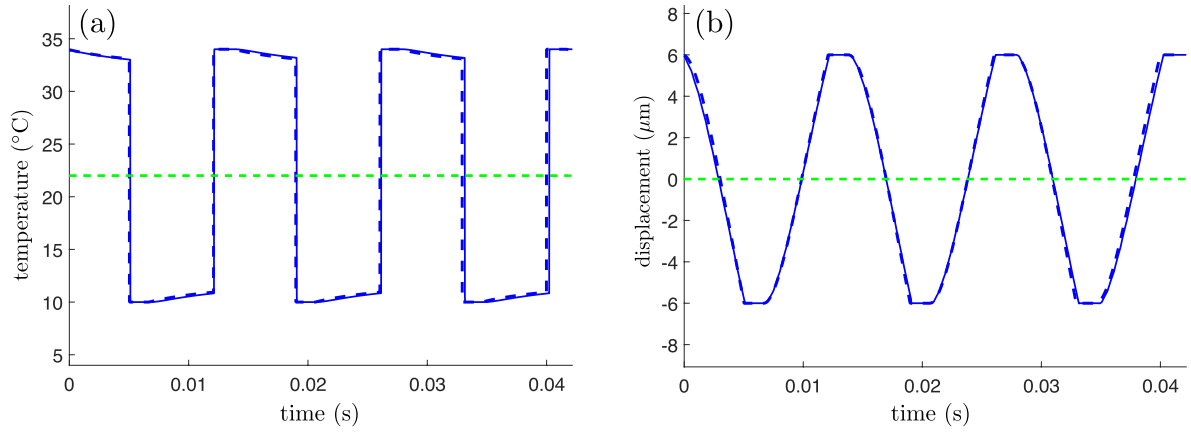

Figure 6. Simulation results of the (a) temperature and (b) displacement at the center of the capacitor with constrained motion and presence of damping. Reduced-order model: dashed lines. Ansys: solid lines. The contact between the pyroelectric capacitor and the thermal reservoirs is modeled by imposing the corresponding limits on the displacement of the capacitor.

4.3. Heat transfer

The heat model is based on dividing the device into three different zones as depicted in figure 3: the pyroelectric plate, the tethers, and the bimetal cantilever. The model also takes into account the thermal resistance of the gas film between the capacitor and the thermal reservoirs. Each zone is modeled by the discretized 1D heat equation (along the dominant component of the heat flux) using second order central difference scheme for the diffusion term and first order explicit time integration scheme, as presented next for the capacitor. Similar discretizations were carried out for the tethers and bimetal cantilevers in the y and x directions respectively.

The pyroelectric capacitor temperature, $T_c(z,t)$, is assumed to be uniform in the $(x-y)$ plane of the capacitor. Its variation along the z direction is captured by discretizing the capacitor into layers in the $x-y$ plane, where the energy balance for layer i of thickness Δz is governed by

$$\rho_c c_c \Delta V_i \frac{T_c(z_i, t+\Delta t) - T_c(z_i, t)}{\Delta t} = \dot{Q}_i^{\leftarrow} - \dot{Q}_i^{\rightarrow} \quad (19)$$

where $\Delta V_i = L_c b_c \Delta z$. For the interior nodes, the rates of heat transfer into and out of the layer are

$$\dot{Q}_i^{\leftarrow} = k_c A_c \frac{T_c(z_{i+1}, t) - T_c(z_i, t)}{\Delta z_c},$$

$$\dot{Q}_i^{\rightarrow} = k_c A_c \frac{T_c(z_i, t) - T_c(z_i - 1, t)}{\Delta z_c} + \delta_{ii*} \frac{T_c(z_i, t) - T_t(1, t)}{R_{ii*}}$$

where $A_c = L_c b_c$, $A_t = b_t t_t$, i^* refers to capacitor element i in contact with tether with intersection area A_{ii*}, δ is the Kronecker's Delta, and the thermal resistance $R_{ii*} = \frac{\Delta y_t/2}{k_t (4 A_{ii*})} + \frac{t_c/2}{k_c (4 t_c^2 (A_{ii*}/A_t))}$. For $i = N_p$,

$$\dot{Q}_i^{\leftarrow} = \frac{T_H - T_c(N_p, t)}{R_H + \frac{\Delta z_c/2}{k_c A_c}}, \quad (20)$$

and for $i = 1$,

$$\dot{Q}_i^{\rightarrow} = \frac{T_c(1, t) - T_L}{R_L + \frac{\Delta z_c/2}{k_c A_c}} \quad (21)$$

where R_H and R_L are the thermal resistances of the gas film between the capacitor and the high and low temperature reservoirs respectively. Referring to figure 1, these resistance are approximated as

$$R_H = \frac{min(g)}{k_g(1-\chi)A_c} \parallel \frac{max(g)}{k_g \chi A_c} \quad (22)$$

$$R_L = \frac{min(g')}{k_g(1-\chi)A_c} \parallel \frac{max(g')}{k_g \chi A_c} \quad (23)$$

where χ is the fraction of the capacitor area that is exposed to trenches and $g' = H - g$.

5. Dynamic operation

In this section, we explore key aspects of the dynamic behavior of the device using Ansys simulations of the coupled thermo-mechanical behavior. Understanding the dynamic operation of the device is essential for identifying the key design considerations which will in turn enable tightening the ranges of design parameters used in the design optimization procedure presented in section 6 . The properties of the materials comprising the bimetal cantilever layers, tethers, and pyroelectric capacitor for all the designs considered in this work are presented in table 1. Note that these materials are commonly used in MEMS devices [2]. To aid the discussion in this and the following section, we employ a device with dimensions listed in table 2. The gap separating the reservoirs and the temperature difference between the two reservoirs are selected to be $H = 20~\mu m$ and $T_H - T_L = 24~°C$.

Figures 5(a) and (c), which respectively plot the time evolution of the temperature and the displacement of the center of the capacitor, show that the device operates at a frequency of ~30 Hz. Figure 5(b) shows the time evolution of the temperature at a point on the bimetal cantilever located at a distance of 200 μm from the capacitor. State b corresponds to the time instant of contact between the capacitor and the LTR where the contacting capacitor surface temperature reaches that of the LTR ($T_L = 10~°C$). Upon contact, the capacitor cools rapidly
Figure 7. Simulation results for design #7 of table 3 over a complete cycle at the quasi-stationary state. The color denotes the temperature.

($b \rightarrow c$) and reaches the temperature of the reservoir in almost 5 μs. The speed of this heat transfer is in accordance with that predicted by the time scale analysis, equation (24). At state c, the capacitor detaches from the reservoir as a result of the pull force induced by the cooling of the bimetal cantilevers. Once it detaches, the capacitor starts absorbing heat from the bimetal cantilevers which explains the capacitor temperature increase over the period $c \rightarrow d$ in figure 5(a) and the corresponding bimetal cantilevers temperature decrease in figure 5(b). At state d, the capacitor contacts the HTR. The reservoir temperature then rises quickly ($d \rightarrow a$) to that of the HTR. Once the temperature of the bimetal cantilevers increases sufficiently, the capacitor is pulled from the HTR (state a in figure 5(d)) and moves until it contacts the LTR at state b. This completes the cycle (an example is presented in figure 7, which shows the capacitor position every one eighth of the cycle period for design #7 of table 3). The plots of figures 5(a), (b) and (d) correspond to the damped response, where a damping coefficient of $b = 4 \times 10^{-4}$ μN · s · μm^{-1} was introduced to remove the natural structural oscillations. In the absence of damping, the capacitor center displacement is plotted against time in figure 5(c). When compared with the damped response

of figure 5(d), one can observe that the undamped response exhibits high frequency oscillations about the damped response of figure 5(d). The frequency of these oscillations is about 1120 kHz, which is within 10% of the frequency (1265 kHz) of the highest energy mode of vertical translational oscillations predicted by modal analysis in Ansys.

Upon inspecting figure 5, it can be seen that the operation cycle is not symmetric, with process $c \rightarrow d$ taking longer than process $a \rightarrow b$. This asymmetry can be explained by investigating the associated mechanical behavior. To this end, the simulations were carried out without imposing any mechanical boundary condition on the displacement of the capacitor at contact with the thermal reservoirs. Upon contact with the HTR at state d (figure 5(d)), the elevation of the capacitor increases toward e, indicating that the thermal inertia of the bimetal cantilevers and the capacitor kept pushing the capacitor through the HTR until state a is reached, at which point the capacitor is pulled away from the HTR toward the LTR. This behavior, observed when the capacitor reaches the HTR, is a consequence of its rapid lateral thermal expansion as it receives heat from the reservoir. This deformation imparts a moment on the bimetal cantilevers that causes them to deflect

J. Phys. D: Appl. Phys. **53** (2020) 195501

T Gebrael *et al*

upwards between points *d* and *e* (figure 5(d)). As heat continues to diffuse into the bimetal cantilevers, bending starts to take effect. Consequently, the bimetal cantilevers start deflecting downward once state *e* is reached (figure 5(d)). In contrast, at the impact with the LTR, the lateral thermal contraction of the pyroelectric capacitor upon cooling imparts a moment that also deflects the bimetal cantilevers upward. This effect adds to the upward bending of the bimetal cantilevers as they lose heat to the capacitor. Hence, the capacitor does not fall below the LTR and the duration separating states *b* and *c* is smaller. In addition, the vertical force that arises from expansion/contraction of the pyroelectric capacitor and the bimetal cantilevers significantly contributes to the observed asymmetry in the travel time. If the tethers are sufficiently stiff in the *x*-direction, this force will add to the upward force during process *c* − *d* and will oppose the downward force during process *a* − *b*. A schematic is presented in figure A3 of section A.2 of the appendix.

We conclude this section by pointing out that increasing the operation frequency is a key design objective, since the power output is the product of the work produced per cycle (equation (4)) and the operation frequency. To increase the operating frequency, the design is modified so that the asymmetry between the durations *b* − *c* − *d* and *d* − *a* − *b* of figure 5(c) is significantly reduced. This is realized by increasing the *x*-bending compliance of the tethers by a factor of 10 without affecting the heat transfer dynamics through the tethers. This may be accomplished by reducing the tether width by a factor of $\sqrt{10}$ and increasing its height by the same factor. Reducing the *x*-bending stiffness of the tethers will diminish the contribution of the thermal expansions/contractions of the capacitor/tethers to the vertical force on the capacitor. Instead, these expansions/contractions will contribute to tethers deflections. Figures 6(a) and (b) show that, upon reducing the tether *x*-bending compliance and placing stops at the locations of the LTR and the HTR reservoirs, the operation cycle is nearly symmetric and the frequency increased from 30 Hz to 75 Hz. The plots show that the response predicted by the reduced order model, presented in section 4, is in good agreement with that predicted by Ansys simulation. Figures 7 and 8 show the capacitor position and bimorph deflection design #7 of table 3. The colors in the two figures refer respectively to the temperature and pressure distributions.

6. Design considerations

In this section, we discuss design considerations based on the time scales characterizing heat transfer and structural dynamics. We also discuss the necessary conditions for sustained oscillation of the device, and answer the question of whether these sustained oscillations can take place at the mechanical resonance frequency. Based on the discussion, we present in appendix B a simple design procedure that yields preliminary dimensions which serve as starting values for the optimization algorithm wrapped around the model presented in section 4.

Figure 8. Simulation results for design #7 of table 3 over a complete cycle at the quasi-stationary state. The color denotes the departure from the average enclosure pressure in the squeezed film.

Crucial to sustained oscillations of the pyroelectric capacitor is designing for the relation between τ_c, the time it takes the capacitor to store internal energy by heat transfer from the HTR, and τ_s, the time it takes the bimetal cantilevers to pull the capacitor away for the reservoir. For sustained oscillations, the capacitor must store a sufficient amount of internal energy before it detaches from the HTR. After separation, the thermal energy stored in the capacitor continues to heat the bimetal cantilevers which, in turn, exert a force on the capacitor that pushes it toward the LTR. The energy stored in the capacitor must be such that the heat gained by the bimetal cantilevers is sufficient to push the capacitor all the way to the LTR. Similar arguments can be made for detachment from the LTR and subsequent travel to the HTR. The time scale τ_c is estimated by balancing the capacitor's change in internal energy with the heat transferred by conduction through the thickness of the capacitor

$$\tau_c \sim \frac{t_c^2}{\alpha_c} \tag{24}$$
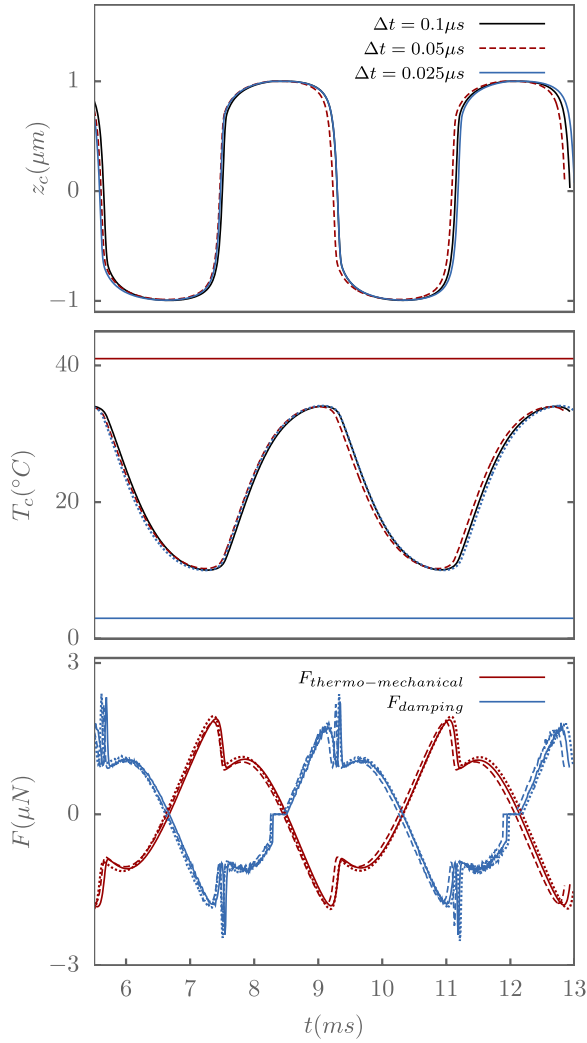

Figure 9. Impact of the time step size on the convergence at quasi-stationary state.

where t_c is thickness of the pyroelectric capacitor, and $\alpha_c \equiv \frac{k_c}{\rho_c c_c}$ is the thermal diffusivity of the pyroelectric material.

In order for the capacitor to detach from the thermal reservoir, the force exerted by the bimetal cantilevers on the capacitor should switch its direction so that it pulls the capacitor away from the reservoir. How quickly this force reverses its direction depends on the change in the bimetal cantilevers temperature. In estimating τ_s, the time scale required for such a change to take place, we assume that the bimetal cantilevers force needed to detach the capacitor from the thermal reservoir develops over the time it takes the heat from the capacitor, flowing through the tethers, to diffuse along a fraction of the bimetal cantilever length, L_b^*. The resulting change in average temperature of this portion (of length L_b^*) of the bimetal cantilever is ΔT^*. The time scale τ_s can then be estimated from the balance

$$\frac{T_c - T_b^*}{R_t + R_b^*}\tau_s = \rho_b c_b A_b L_b^* \Delta T^* \qquad (25)$$

where $R_t = \frac{L_t}{4k_t A_t}$ and $R_b^* = \frac{L_b^*}{2k_b A_b}$ are respectively the thermal resistances of the tethers and bimetal cantilevers portions of

length L_b^*. Note that introducing the tethers adds to the degrees of freedom so that we can adjust τ_s by changing $L_t/(k_t A_t)$, provided that $(b/t)_t \ll 1$ and $(b/L)_t \ll 1$. The tethers may be thought of as thermal resistors that can be designed to regulate the flow of heat between the pyroelectric capacitor and the bimetal cantilevers.

Hence, in order to maintain the device's oscillations the following condition should be satisfied:

$$\frac{\tau_c}{\tau_s} \ll 1 \Rightarrow \frac{t_c^2}{L_b^{*2}} \frac{\alpha_b}{\alpha_c \left(1 + \frac{R_t}{R_b^*}\right)} \ll 1. \qquad (26)$$

For the materials listed in table 1, $\alpha_b/\alpha_c = 1.27$. If L_b^* is such that the thermal resistance of the tethers is much less than that of the bimetal cantilevers of characterisitc length L_b^*, then a necessary condition for the cyclic operation of the device to be sustained is

$$t_c \ll L_b^* \text{ when } R_t \ll R_b^*. \qquad (27)$$

Note that L_b^*/L_b is primarily dependent on ΔT and on $H - t_c$, the travel distance of the pyroelectric capacitor between the two reservoirs.

We point out when condition $R_t \ll R_b^*$ is satisfied, the time scale limiting the cycling frequency of the device is τ_b; the time scale of thermal diffusion along the bimetal cantilever,

$$\tau_b \sim L_b^2 \left(\frac{\rho c}{k}\right)_b. \qquad (28)$$

For the dimensions listed in table 2, $\tau_c = 1.1$ μs, $R_t/R_b = 0.1$, and $\tau_b = 13.58$ ms. Since τ_b is the time scale limiting the cycling operation of the device, the cycling frequency is of the order $1/\tau_b = 71$ Hz, which is close to the frequency predicted by the simulations presented in figure 6.

As previously mentioned, structural mechanics considerations require the tethers to have a small torsional stiffness and a bending stiffness in the x-direction that is much smaller than that of the bimetal cantilever. This can be satisfied by choosing the tether width b_t to be as small as possible and selecting its length and thickness such that $b_t/L_t < 0.15$, $t_t/b_t > 4$, and $t_t(b_t/L_t)^3 \ll b_b(t_b/L_b)^3$. In order for the pyroelectric capacitor to travel the entire distance separating the two reservoirs, the thermal expansion contribution to the force acting on the capacitor must be larger than the restoring elastic component. Referring to equation (10), the length of the bimetal cantilever must be chosen to be sufficiently large. Note however, that choosing L_b to be too large results in reduction in the speed of the device. This is because $\tau_b \propto L_b^2$ (see equation (28)). The pyroelectric capacitor thickness, t_c, must be sufficiently large so that it behaves as a rigid body. Dimensions of the pyroelectric capacitor should be carefully chosen as they also affect the thermal behavior (see equation (24)), the pyroelectric effect and the resulting power output (equations (4)–(8)), and the damping force (equation (18)).

Referring to equation (5), the power output is proportional to the frequency, volume of the pyroelectric capacitor, and the difference in temperature between the HTR and the LTR. Here we investigate the conditions of maximizing the frequency for given pyroelectric capacitor volume and material

properties of the pyroelectric capacitor, tethers, and bimetal cantilever layers. We also answer the question of whether the device can operate at the mechanical resonance frequency. Increasing the operation frequency can be accomplished by reducing the bimetal cantilever length (equation (28)), which in turn requires decreasing the tether's length and pyroelectric capacitor thickness, as required by conditions (equation (27)) and (equation (26)). Due to the requirement of large bending compliance in the x-direction, we expect the tethers width to be the smallest dimension in the device. Thus, the minimum dimension allowed by the fabrication process puts an upper bound on the maximum operation frequency of the device. In addition, reducing the pyroelectric capacitor thickness while keeping its volume constant requires increasing its planar area proportionally, which increases the gas damping force. In order for the device to operate at the mechanical resonance frequency, we require $f_{res}\tau_b \sim 1$ where the resonance frequency is $f_{res} \simeq \frac{1}{2\pi}\sqrt{\frac{2\kappa_b}{m_c}}$ and the bending stiffness of a single bimetal cantilever is $\kappa_b = \frac{3(EI)_{eq}}{L_b^3}$. Note that, by design, the contribution of the tethers to the stiffness is negligible. For the material properties listed in table 1, and choosing $b_1 = b_2$ and $t_2/t_1 = \sqrt{E_1/E_2}$, the condition reduces to
Figure 14. Dependence of the energy generated per cycle on the difference in temperature between the HTR and the LTR for the cases listed in table 3.
Figure 15. Dependence of power generated per unit volume on the difference in temperature between the HTR and the LTR for the cases listed in table 3.

$$9.3685 \, t_b \sqrt{V_b/V_c} \simeq 1, \tag{29}$$

where $t_b = t_1 + t_2$ is the total thickness of the bimetal cantilever in μm, and V_b and V_c are respecively the volumes of the bimetal cantilever and the capacitor. It can then be shown that the resonance frequency, which in this case is the same as the operating frequency, is related to the length ($L_b(\mu$m)) of the bimetal cantilever as

$$f_{\text{res}} = \frac{7.050 \times 10^7}{L_b^2}. \tag{30}$$

In section A.3 of the appendix, we present a design procedure to estimate the device dimensions so that it operates at the mechanical resonance frequency for a given $T_H - T_L$ and H. This procedure, along with the design considerations discussed above, were used to explore and explain the qualitative dependence on $T_H - T_L$ of the bimetal cantilevers length (figure A4), operating frequency (which is equal to the mechanical resonance frequency) (figure A4), and the length of the pyroelectric capacitor (assumed to have a square shape) for different values of distance separating the two reservoirs (figure A5) . These dependences for different values of the travel distance are also discussed and presented in figures A11–A13.

We conclude by pointing that that the trends presented in figures A4–A13 are only qualitative since the design procedure is not based on the dynamic solution of equation (9). The procedure also does not include the tethers or the damping force, and as such, serves only to gain physical insight and to provide initial values of the geometrical parameters to be used in the optimization algorithm that incorporates a numerical solver of the reduced order dynamic model presented in section 4. The optimization algorithm is used to arrive at device dimensions that maximize the output work, as discussed in section 8.

7. Validation of the model

Validation of the reduced order model was carried out in three phases. In the first phase, the heat transfer and the bimetal cantilever tether force models were validated by comparing with Ansys simulations, as presented in figures A1 and A2 of section A.1 in the appendix. In the second phase, validation of the coupled thermo-mechanical model was carried out by comparing with Ansys simulations the dynamic behavior of the device of dimensions listed in table 2. Other conditions are stated at the end of section 5. The comparison presented in figure 6 for the change with time of the capacitor temperature and displacement over three operation cycles at the quasi-stationary state shows that the reduced order model accurately predicts the dynamic behavior of the device. The third phase entails choosing the time step and spatial resolution used in the model as a tradeoff between accuracy and cost. Impact of the computational time step on the accuracy of the scheme is assessed for design #7 of table 3 in terms of time evolution of the pyroelectric capacitor position, average temperature, and the damping and thermo-mechanical forces. As can be seen from figure 9, choosing $\Delta t = 0.1 \, \mu$s yields a sufficiently accurate solution. Noting that for this case, the operating frequency is highest (291 Hz from figure 12), we chose $\Delta t = 0.1 \, \mu$s for all the other cases. As for the mesh size, choosing $\Delta x = \Delta y = b_{tr}/10$ yielded a damping force that is nearly independent of the mesh size.

8. Optimal designs

The simple design procedure presented in section A.3 of the appendix serves to provide the dynamic solver with initial guesses of the various dimensions. The solver, which is based on the model presented in section 4, simulates the thermo-mechanical dynamic operation, accounting for the heat transfer between the reservoirs, capacitor, and bimetal cantilevers, and for the thermo-mechanical, torsion and damping forces imparted on the capacitor respectively by the bimetal cantilevers, the tethers, and the surrounding gas. Equation (9) is numerically solved using a first order explicit time stepping scheme. Computing the damping force by integrating equation (18) requires solving equation (16) numerically. Being

the most expensive step, numerical solution of equation (16) is carried out in parallel using OpenMP where the computational mesh is distributed among the CPU cores.

As shown in figure 10, the solver is embedded in an optimization algorithm that maximizes the work produced per unit volume (equation (8)) while meeting the various constraints imposed by the reduced order model. For example, all the optimal designs presented below satisfy the condition $\frac{E_b b_b (t_b/L_b)^3}{E_t t_t (b_t/L_t)^3} > 18$, which guarantees a sufficiently larger bending compliance (in the *x*-direction) of the tethers. The optimization algorithm employs a basic incremental search along all the design coordinates. Once an improved design is identified, the incremental search starting from the new improved design is repeated. The procedure continues until no further improvement is reached. Figure 11 shows a plot of the power density (cost function) versus the optimization iteration counter for design #7 of table 3. We point out here that gradient-based optimization approaches did not offer any advantages due to the fact that the solution space is not only noncontinuous, but rather patchy. Nearly optimal designs were obtained using the optimization algorithm for different values of $T_H - T_L$. The various dimensions of these designs are listed in table 3.

As shown in figure 12, the operation frequency increases with temperature difference between the two reservoirs, in accordance with the discussion in section 6. The operation frequency ranges from 183 Hz for $T_H - T_L = 26\,°C$ to 291 Hz for $T_H - T_L = 38\,°C$. Since the pyroelectric capacitor does not get in contact with either reservoir but rather reaches within a distance of g_{min}, we expect that ΔT_p, the peak to peak change in the average capacitor temperature over a cycle, to be less than $T_H - T_L$. The plot presented in figure 13 shows that ΔT_p increases linearly with $T_H - T_L$, with the ratio $\Delta T_p/(T_H - T_L)$ being nearly a constant of $\sim$0.6. The energy produced per cycle, $\dot{\omega}^{\rightarrow}/f$, is plotted against $T_H - T_L$ in figure 14. It follows a linear trend similar to ΔT_p, which follows from equation (8). The power density per unit volume, expressed in equation (8), increases quadratically in $T_H - T_L$, as seen in the plot of figure 15. As $T_H - T_L$ increases from 26 to 38 °C, the power density increases from 208 to 450 mW

cm^{-3}. For the considered range of $T_H - T_L$, the power generated per unit surface area ranges from 0.4 to 0.65 *mW/cm*^{2}, as presented in figure A7 of appendix C. These values are compared with power density values of energy harvested from other environmental sources in table 4.

Impact of the separation between the HTR and the LTR, while keeping fixed the total thickness of the gas film (travel distance for the capacitor), is discussed in section A.4.1 of the appendix. Finally, the impact of increasing the total thickness of the gas film (travel distance for the capacitor) is discussed in section A.4.2 of the appendix.

9. Conclusion

In this study, a new design of a MEMS pyroelectric energy harvester is proposed. During cyclic operation of the device, the pyroelectric capacitor plate remains parallel to the thermal reservoirs, which not only increases the rate of heat transfer across the gap, but also ensures nearly uniform temperature within the capacitor. This operation is enabled by the use of tethers of low torsional stiffness to connect the bimetal cantilevers to the plate. Investigation of various time scales key to thermo-mechanical operation of the device uncovered the conditions for self-sustained oscillations and the conditions for these oscillations to take place at the mechanical resonance frequency (in the absence of gas damping). The physically-based reduced order model was employed to identify the length of the bimetal cantilever beams as a key design parameter. When embedded within an optimization algorithm, the model was used to arrive at device dimensions for nearly optimal power generation while operating in the self-sustained oscillations/contact-free operation regime. As the temperature difference between the two reservoirs increases from 26 to 38 °C, the power density harvested increased from 0.4 to 0.65 mW cm^{-2}.

The proposed design along with the design methodology presented fill a gap in the under-explored area of MEMS pyroelectric energy harvesters, which brings us one step closer to realization of these devices.

Acknowledgments

Appendix. Supplementary material

A.1. Validation of the reduced order model

The model is compared with Ansys simulations for the unsteady case where the initial temperature is 30 °C. The boundary conditions are such that all the faces of the capacitor plate, tethers, and bimetal cantilevers in contact with the surrounding gas are insulated, and the plate surface in contact with the heat reservoir is assigned a fixed temperature equal to that of the reservoir, 10 °C. The dimensions used for the comparison are listed in table A1. The comparison, presented in figure A1, shows a good agreement between the heat transfer model and Ansys. The model accuracy is expected to increase as the number of computational elements is increased and the time step is reduced.

In figure A2, the bimetal cantilever force, computed from the model presented above, is compared to that predicted from simulating the device, including the tethers. The plot shows dependence of the total vertical force applied by both bimetal cantilevers on the pyroelectric capacitor when subjected to a uniform temperature (that differs by ΔT from the reference temperature) and a vertical tip deflection, Δy. The material properties and dimensions used are listed in tables 1 and 2. The steady state experiments were performed in Ansys structural by imposing a uniform temperature on the bimetal cantilevers and a displacement of the capacitor. The vertical force calculated by the solver is then obtained from a probe attached to the capacitor. The temperature differences ΔT shown in figure A2 are measured with respect to a reference temperature of 22 °C. As can be seen in figure A2, the reduced order model is accurate over a considerable range of deflections and excitation temperatures.

A.2. Asymmetry

Figure A3 aids to explain the asymmetry between the two halves of the operation cycle that arises from the effect of the thermal expansion/contraction of the capacitor and bimetal cantilevers on the vertical force acting on the capacitor.

A.3. Simple design procedure

Now we present a design procedure to estimate the device dimensions so that it operates at the mechanical resonance frequency for a given T_H, T_L and H. Choosing $b_1 = b_2$ and $t_2/t_1 = \sqrt{E_1/E_2}$ for the bimetal cantilevers and starting from the state where the pyroelectric capacitor was in contact with the HTR and is just about to detach. The procedure is as follows:

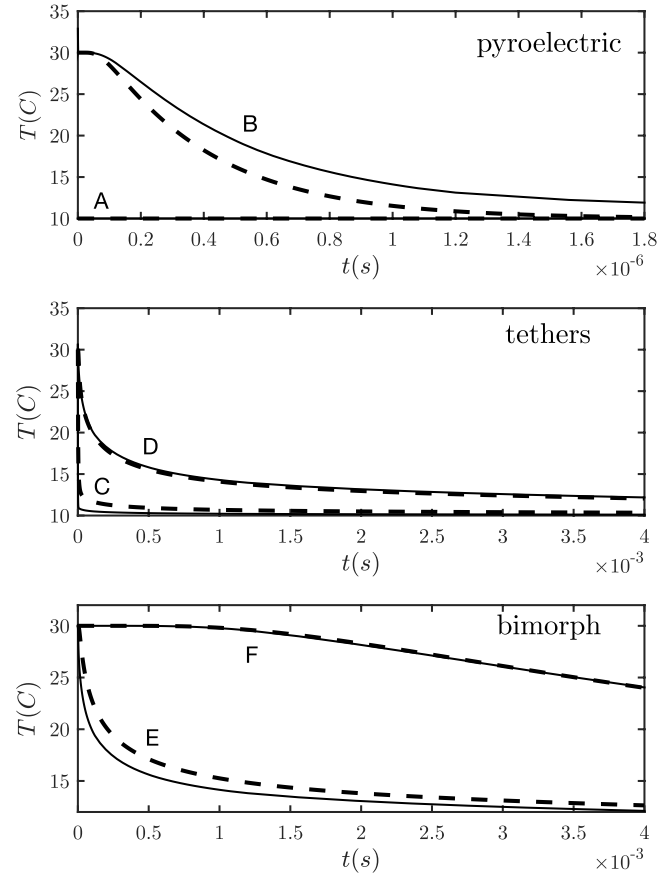

Figure A1. Plot of the temperature versus time at locations *A*: face of pyroelectric capacitor where a temperature of 10 °C is imposed, *B*: center of pyroelectric capacitor, *C*: junction at tether-pyroelectric capacitor, *D*: junction at tether-bimetal cantilever, *E*: junction at bimetal cantilever-tether and *F*: fixed edge of bimetal cantilever (insulated). Reduced-order model: dashed lines. ANSYS simulations: solid lines.

Figure A2. Bimetal cantilever-tether force versus deflection at different excitation temperatures (solid lines: model, symbols: Ansys).

(i) Assume the temperature change along the beams ($\Delta T_b(x)$) to vary linearly from $T_H - T_0$ (on the pyroelectric capacitor side) to 0 at the fixed support.

(ii) Find $\frac{z_{tip,exp}t_b}{L_b^2} = f(\Delta T_b(x)) \Rightarrow \frac{L_b^2}{t_b} = \frac{z_{tip,exp}}{f(\Delta T_b(x))}$ using equation (14)

Figure A3. Schematic representing, at different states of the cycle, the effect of the thermal expansion/contraction of the capacitor and bimetal cantilevers on the vertical force acting on the capacitor. The resulting moment imparted on the bimetal cantilevers adds to the downward force when the capacitor is traveling from the HTR to the LTR and reduces the upward force when the capacitor is traveling from the LTR to the HTR. This renders the process (c) and (d) slower than the process (a) and (b).
Figure A4. Variation of the bimetal cantilever length and operating frequency with the difference in temperature between the HTR and the LTR. The travel distance has been kept fixed; $d_{\min} = 2 \ \mu$m.

Figure A5. Variation of the length of the pyroelectric capacitor, assumed to have a square shape, with the difference in temperature between the HTR and the LTR, for different values of distance separating the two reservoirs. The travel distance has been kept fixed; $d_{\min} = 2 \ \mu$m.

(iii) Since $f_{\text{res}} \propto 1/L_b^2$, we maximize f_{res} by setting the travel distance $H - t_c = z_{tip,exp} - \delta = \frac{f(\Delta T_b(x))L_b^2}{t_b} - \delta$ to a minimum, $d_{\min}$.
(iv) It follows that $t_c = H - d_{\min}$ and $L_b^2 = t_b \frac{\delta + d_{\min}}{f(\Delta T_b(x))}$.

electric capacitor is determined as $A_c = V_c/t_c$, where V_c is determined from equation (29).

(vii) The operating (resonance) frequency is estimated from equation (30).

A positive value of δ ensures that the pyroelectric capacitor, once it reaches the reservoir, is still pushed by the thermal expansion of the bimetal cantilever into the reservoir which guarantees contact time long enough for heat exchange. Choosing $T_0 = 22$ °C, $\delta = 1$ μm, $d_{\min} = 2$ μm, and $t_{b,\min} = 5$ μm, and noting that a larger width of bimetal cantilever promotes the stability of the device, we choose $\zeta_b = 3$. The design procedure we just outlined was used to estimate device dimensions for different values of $T_H - T_L$ and H. Plots of the bimetal cantilever length, operating frequency, and pyroelectric capacitor length against $T_H - T_L$ are presented in figures A4 and A5. As the temperature difference between the HTR and the LTR increases, the temperature change experienced by the cantilever is larger so that a bimetal cantilever of a smaller length is needed for the same travel distance. This in turn causes the operating frequency,

Table A1. Device dimensions (μm) used for the comparing the heat model to Ansys simulations.

	Bimetal cantilever layer 1	bimetal cantilever layer 2	Tethers	Pyroelectric capacitor
Length L	1000	1000	70	1000
Width b	20	20	3	200
Height t	2.5	2.5	3	8

Table A2. Dimensions of optimized designs for different H. For all designs, $T_H = 37$ °C , $T_L = 7$ °C, $b_c = 50$ μm, $g_{min} = 0.5$ μm, $X = 1 - b_{tr}/a$, $b_{tr} = 25$ μm, and $t_c = H - 2$ μm. All dimensions are in μm.

Case #	H	d_{tr}	X	L_b	b_b	t_b	L_c	t_c	t_t	b_t	L_t
1	15	3.5	0.305	480	10	5	1880	13	5	1	20
2	16	3.5	0.305	475	10	5	1880	14	5	1	20
3	17	3	0.305	470	10	5	1880	15	5	1	20
4	18	2.75	0.300	465	9	5	1840	16	5	1	20
5	19	2.75	0.300	465	9	5	1800	17	5	1	20
6	20	2.5	0.285	460	9	5	1840	18	5	1	20
7	21	2.5	0.305	460	9	5	1880	19	5	1	20

which is equal to the mechanical resonance frequency, to increase. Figure A5 shows that for a given travel distance (d_{min}) and $T_H - T_L$, increasing the distance separating the two reservoirs results in a pyroelectric capacitor of smaller area. This is because as H increases, the capacitor thickness increases as $t_c = H - d_{min}$ resulting in a smaller area for the same volume. The pyroelectric capacitor area in the $x - y$ plane not only decides on the rate of heat exchange with the reservoirs, but also plays a key role in deciding on the damping force imparted on the capacitor by the surrounding gas.

Note that the simple design procedure just presented is not based on solving equation (9). It also does not include the tethers or the damping force, and as such, serves only to gain physical insight and to provide initial values of the geometrical parameters to be used in an optimization algorithm that incorporates a numerical solver of the reduced order dynamic model presented in section 4.

A.4. Optimal designs

For the designs listed in table 3, the nonlinear dependence of the power density on $T_H - T_L$ is captured in figure A6, where the power density per degree of $T_H - T_L$ increases by $\sim 50\%$ over the $T_H - T_L$ range considered.

We finally note that, for the considered range of $T_H - T_L$, the power generated per unit surface area ranges from 0.4 to 0.65 mW cm^{-2}, as presented in figure A7.

A.4.1. Impact of reservoirs separation.

Next, we investigate impact of H, the separation between the HTR and the LTR. The temperatures of the HTR and the LTR are kept at 37 and 7 °C respectively. The thickness of the pyroelectric capacitor is selected to be $t_c = H - 2$ μm. Other dimensions are listed in table A2. Figure A8 shows that as H increases, the operating frequency decreases. This decrease is, however, small because the gap separating the capacitor from either reservoir is kept constant by adjusting the capacitor thickness according to $t_c = H - 2$ μm. As such,

the distance traveled per cycle is the same for all cases and the slight change in frequency is attributed to the combined effect of a thicker capacitor and shorter bimetallic beams. As H increases from 15 to 21 μm, the peak to peak change in the average capacitor temperature over a cycle decreases by ~ 1.2 °C, according to figure A9. Since both f and ΔT_p decrease as H is increased, the power generated per unit volume decreases by $\sim 10\%$, as shown in figure A10.

A.4.2. Impact of travel distance. So far, the travel distance has been kept fixed; $d_{min} = 2$ μm. As can be observed in figure A11, increasing the travel distance from 2 μm to 8 μm, while keeping the distance separating the two reservoirs fixed ($H = 20$ μm), requires almost doubling the bimetal cantilever length, for $T_H - T_L = 32$ °C. This, in turn, causes the operating frequency to drop from ~ 290 Hz to ~ 90 Hz, as shown in figure A12. Increasing the travel distance also results in a larger pyroelectric capacitor, as demonstrated in figure A13. This is because as the travel distance increases while keeping H fixed, the capacitor thickness decreases as $H - d_{min}$. This, combined with the fact that V_b is larger, requires that the capacitor area be larger (see equation (29)).
